

ASTROPHYSICS OF GW SOURCES: THE COSMIC HISTORY OF STAR AND METAL FORMATION

Binaries that merge in the local Universe originate from progenitor systems that formed at different redshifts and in various environments.

The efficiency of formation of compact binaries is highly sensitive to metallicity of the star formation \Rightarrow detailed comparison of theoretical predictions (rates, mass distributions, *host galaxies*, etc) with GW observations requires knowledge of the distribution of cosmic SFR at different metallicities and times = $\text{SFRD}(Z,z)$.

MEASURING SFR/ M_* WITH GALAXY SURVEYS

Redshift evolution of the FUV/FIR LF and SMF at $0 < z < 4$.

- 24 μm : 20 μJy
 - 100 μm : 1.1 mJy
 - 160 μm : 2.7 mJy
 - 250 μm : 5.7 mJy
 - - 450 μm : 2.4 mJy (ALMA)
 - - 870 μm : 0.3 mJy (ALMA)
 - 850 μm : 5 mJy (SCUBA)
 - 20 cm: 20 μJy
- Without extinction correction:
- $\text{H}\alpha$: $5 \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}$
 - ■ UV: GOODS-S, HUDF

In the absence of dust extinction, UV measurements are more sensitive than current IR or radio data by orders of magnitude!

- Maximum $M/L(z)$ SSP
 - - Minimum M/L constant SFR
- F160W (1.55 μm): 27.0 mag
 - K_s (2.16 μm): 24.5 mag
 - IRAC ch1 (3.6 μm): 26.0 mag

NIR to MIR measurements are critical for deriving stellar masses. Sensitivity to stellar mass depends on the M/L ratio of the stellar population in a distant galaxy, hence on its age, SFH, and extinction.

STAR FORMATION/STARS IN THE UV/IR/FIR

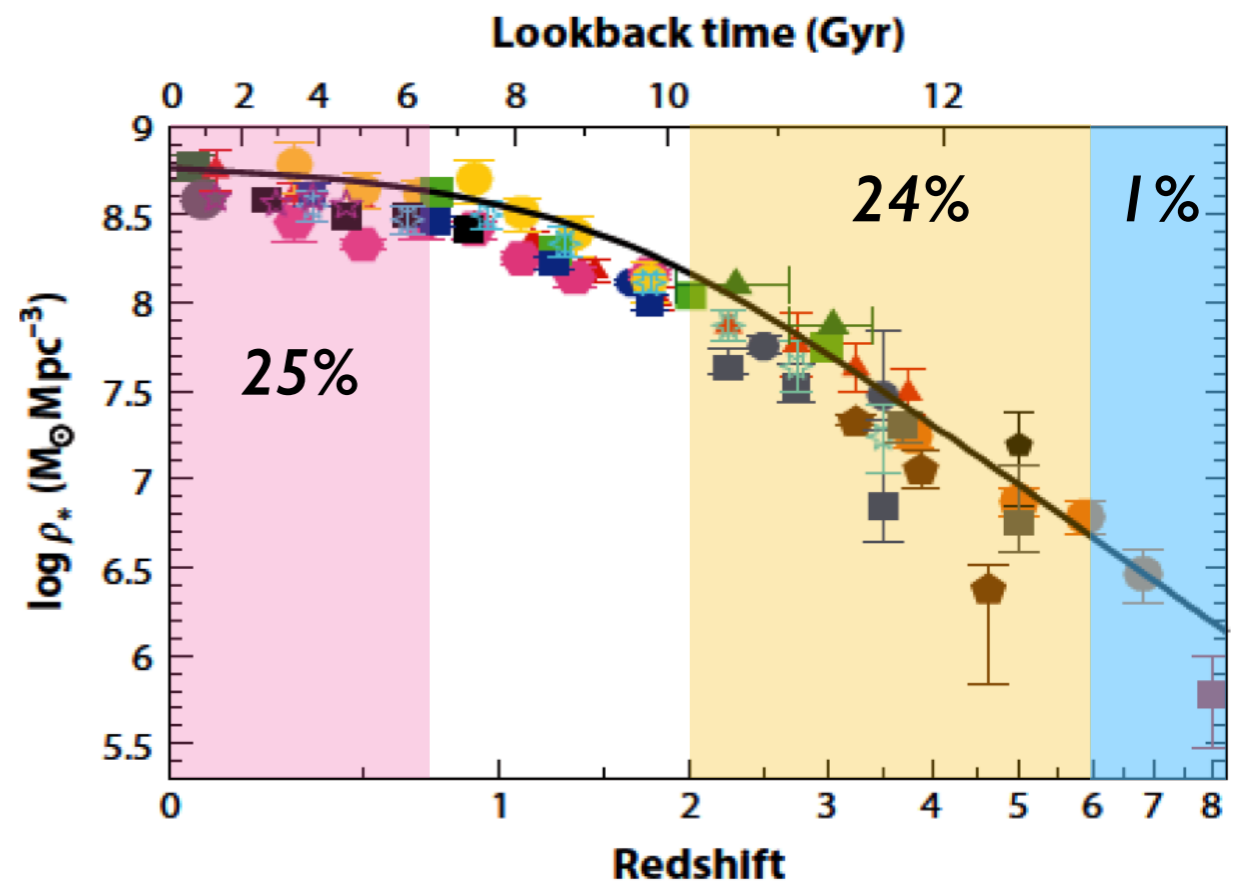

Conversion of light into SFR/ M_* relies on some *basic properties* of stellar populations and dusty starburst galaxies: **UV, FIR** → **SFR** and **NIR/OPT** → **M_*** :

- ✓ **FUV continuum at 1250–1800 Å comes mainly from OB stars.**
- ✓ **FUV luminosity \sim SFR if star formation continues over timescales $>$ few $\times 10^7$ years**
- ✓ **Dust absorbs emission from SF and re-radiates it in the IR.**
- ✓ **Total IR luminosity (8–1000 μm) is a calorimeter for dust-obscured SF.**

COSMIC STAR FORMATION HISTORY

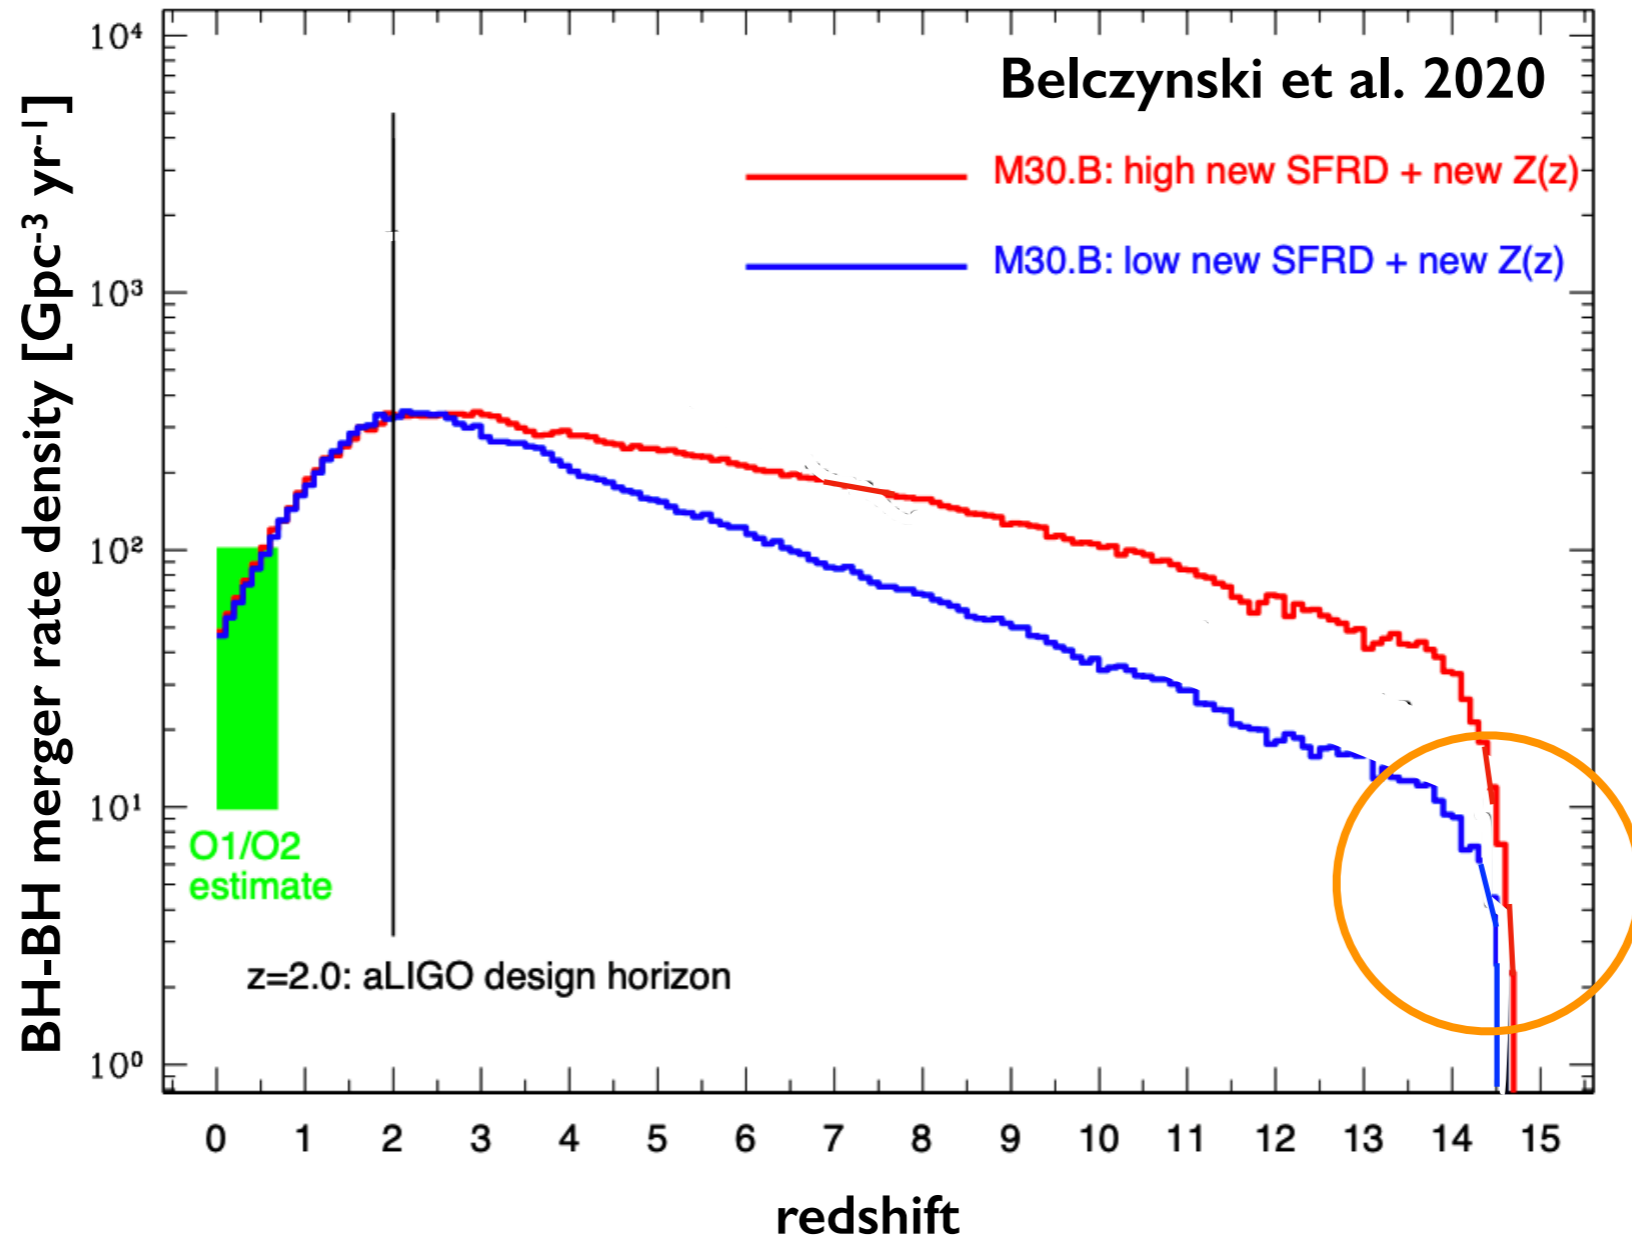

Nice consistency between IR and UV determinations of the SFRD(z) and between the measured SMD(z) and integral of SFRD(z) – *not perfect*, but within measurements spread.

No compelling evidence for non-standard/non-universal IMF!

BH-BH MERGER RATES VS SFH

METALLICITY EFFECTS: $Z(z)$

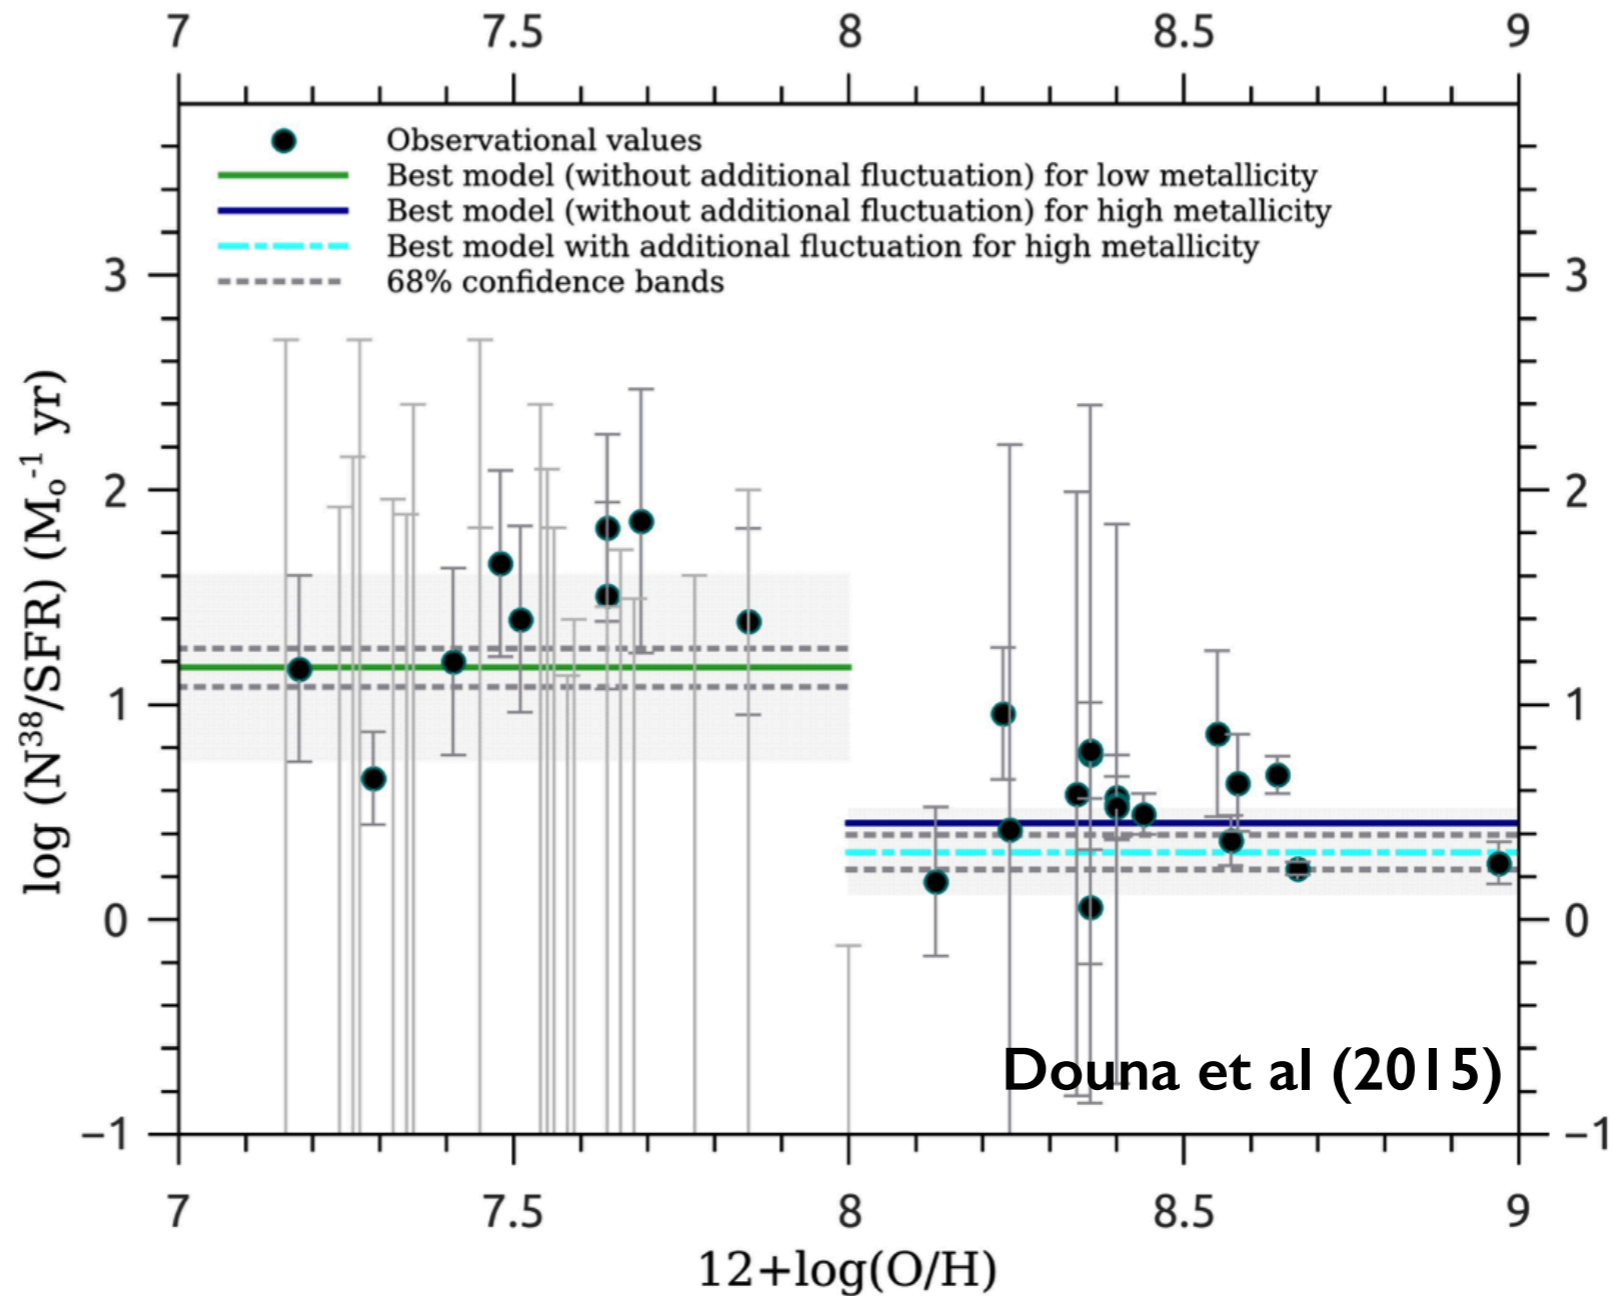

Metallicity affects the number and luminosity of compact binaries through a number of physical processes involved in binary evolution:

- Mass-loss rates of OB and Wolf-Rayet stars from line-driven winds scale inversely with their metal content \Rightarrow a more massive and more numerous black hole population.
- Reduced wind mass losses in low-metallicity environments lead to reduced angular momentum losses and to overall tighter binary orbits, which in turn increase the ratio of *Roche-lobe overflow versus wind-fed binaries*....

2-10 keV X-ray luminosity from HMXBs, per unit SFR, as a function of redshift. Solid line: evolution of this ratio obtained by combining binary population synthesis modeling with a mean stellar mass-gas metallicity relation (see next slide).

METALLICITY DEPENDENCE OF HMXB POPULATIONS

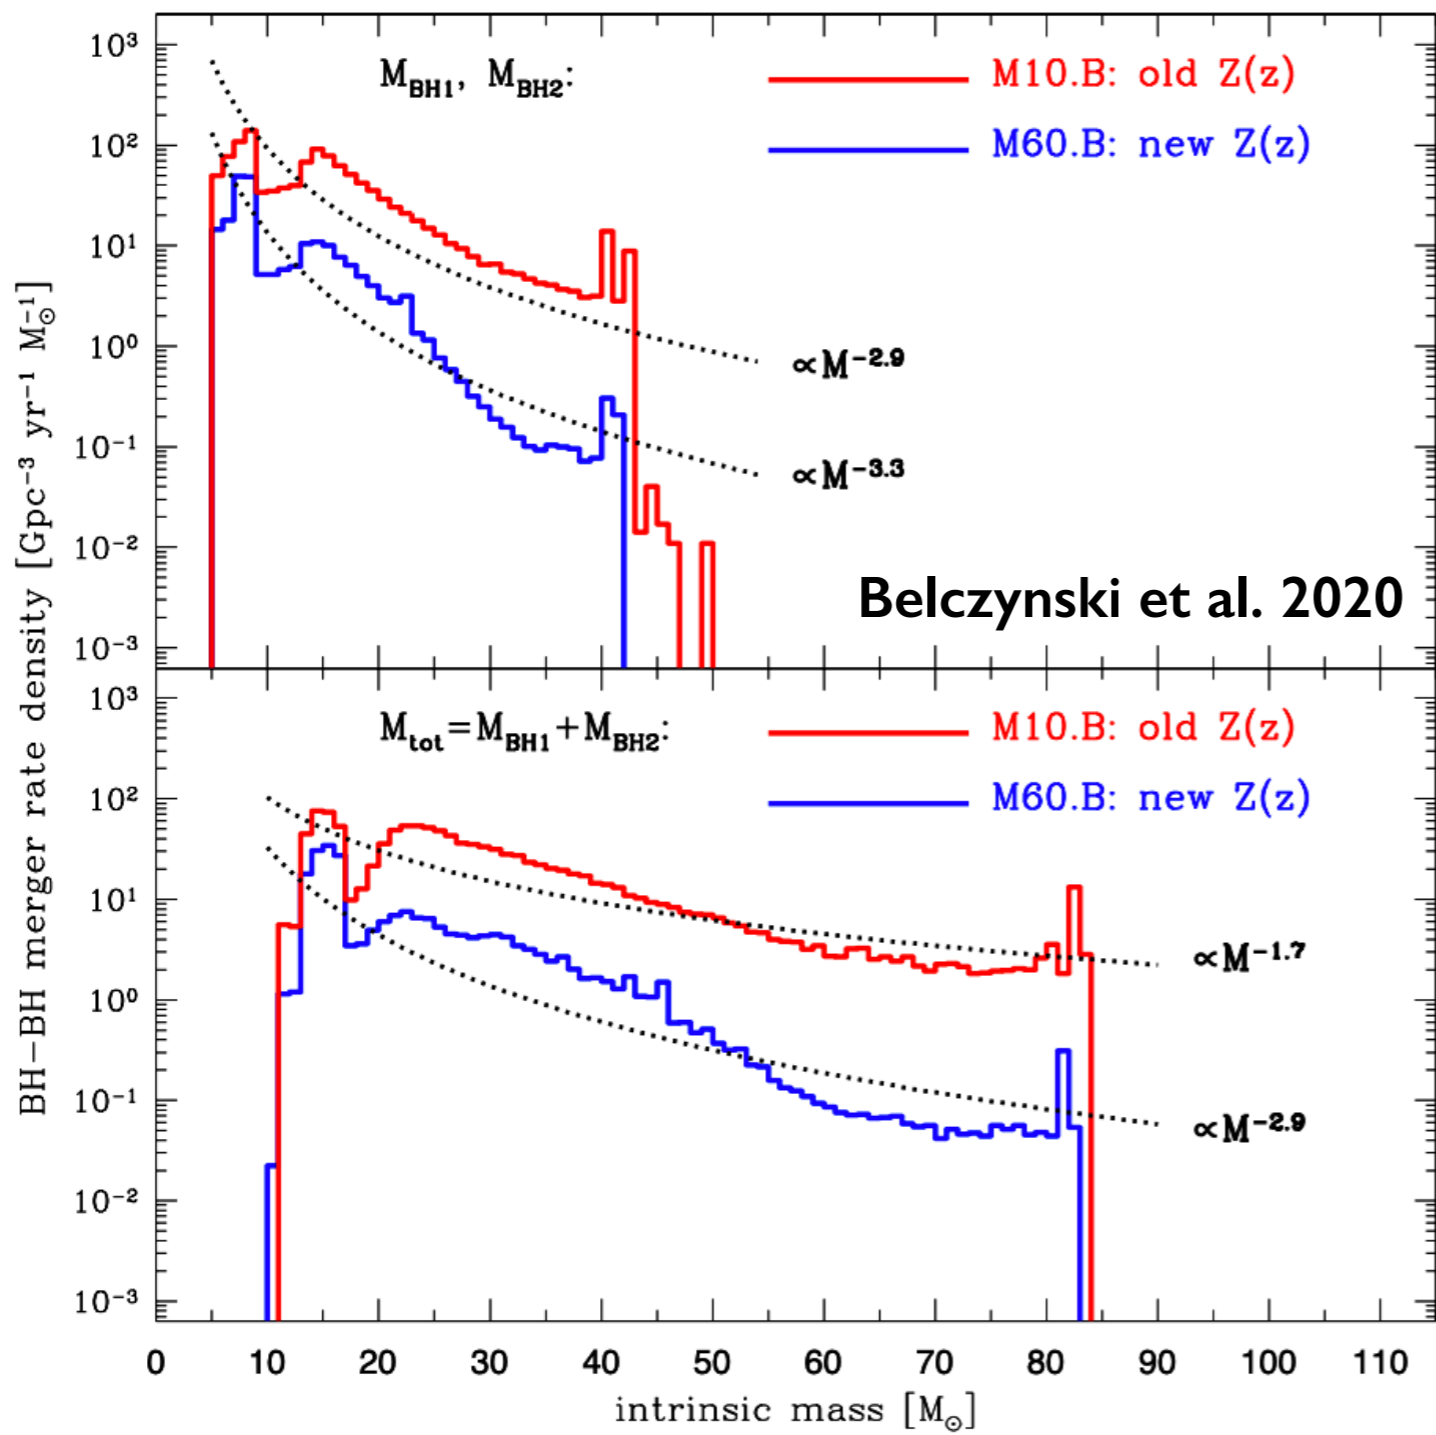

Observed number of HMXBs with luminosities higher than $10^{38} \text{ ergs}^{-1}$, per unit SFR, as a function of the oxygen abundance. Black circles are the data points, with error bars representing Poissonian uncertainties.

MZ relation for $z < 1.6$. The solid curves are the best single-parameter model fits to the MZ relation.

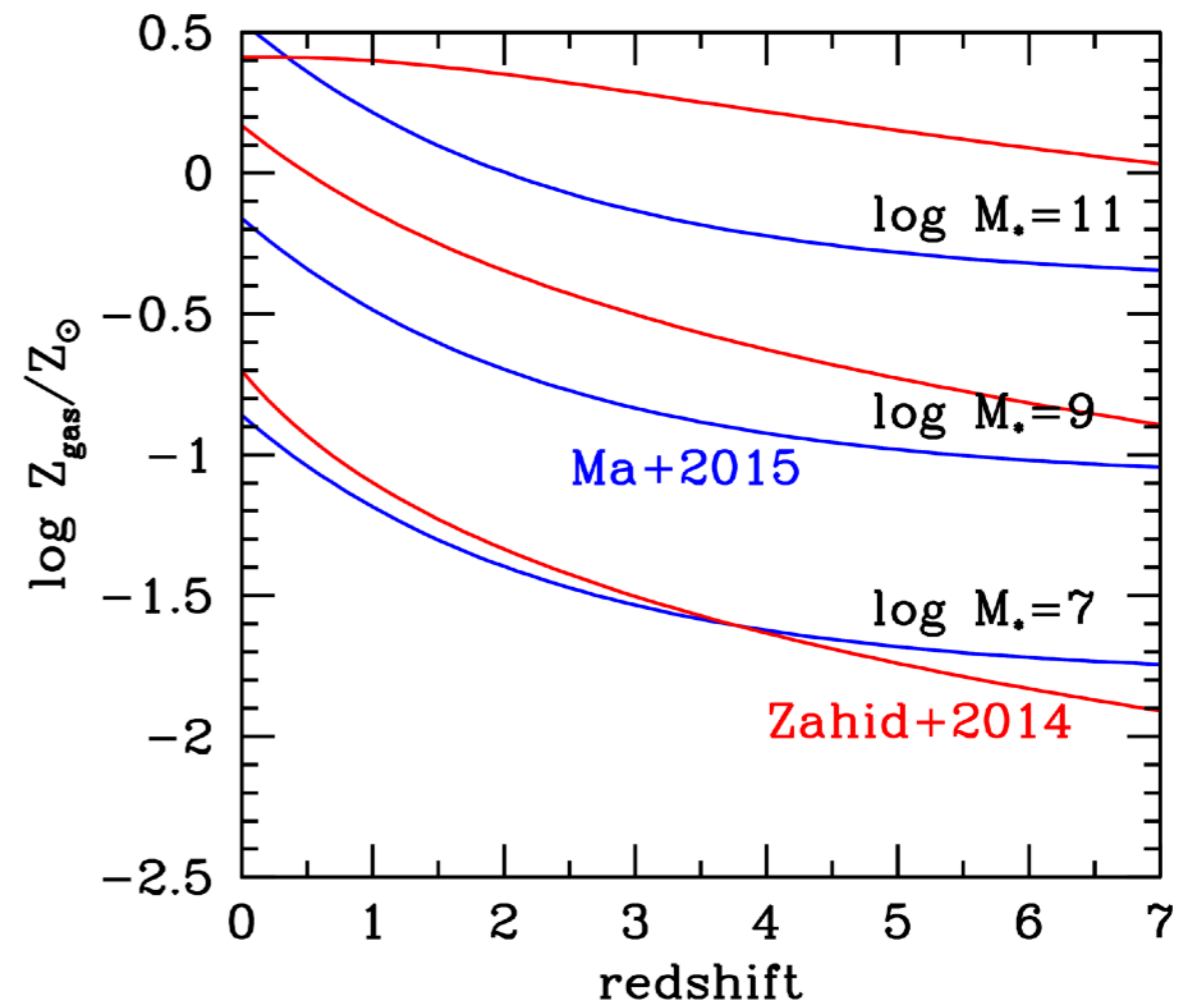

The gas-phase metallicity history of the galaxy population *as a whole*. The **mass-weighted metallicity has been computed by integrating the mass-metallicity relation of [Zahid et al. \(2014\)](#) over the evolving galaxy stellar mass function of [Baldry et al. \(2012\)](#) (blue dot), [Ilbert et al. \(2013\)](#) (red exagons), [Kajisawa et al. \(2009\)](#) (green squares), [Lee et al \(2012\)](#) (magenta stars), and [Grazian et al. \(2015\)](#) (orange pentagons).**

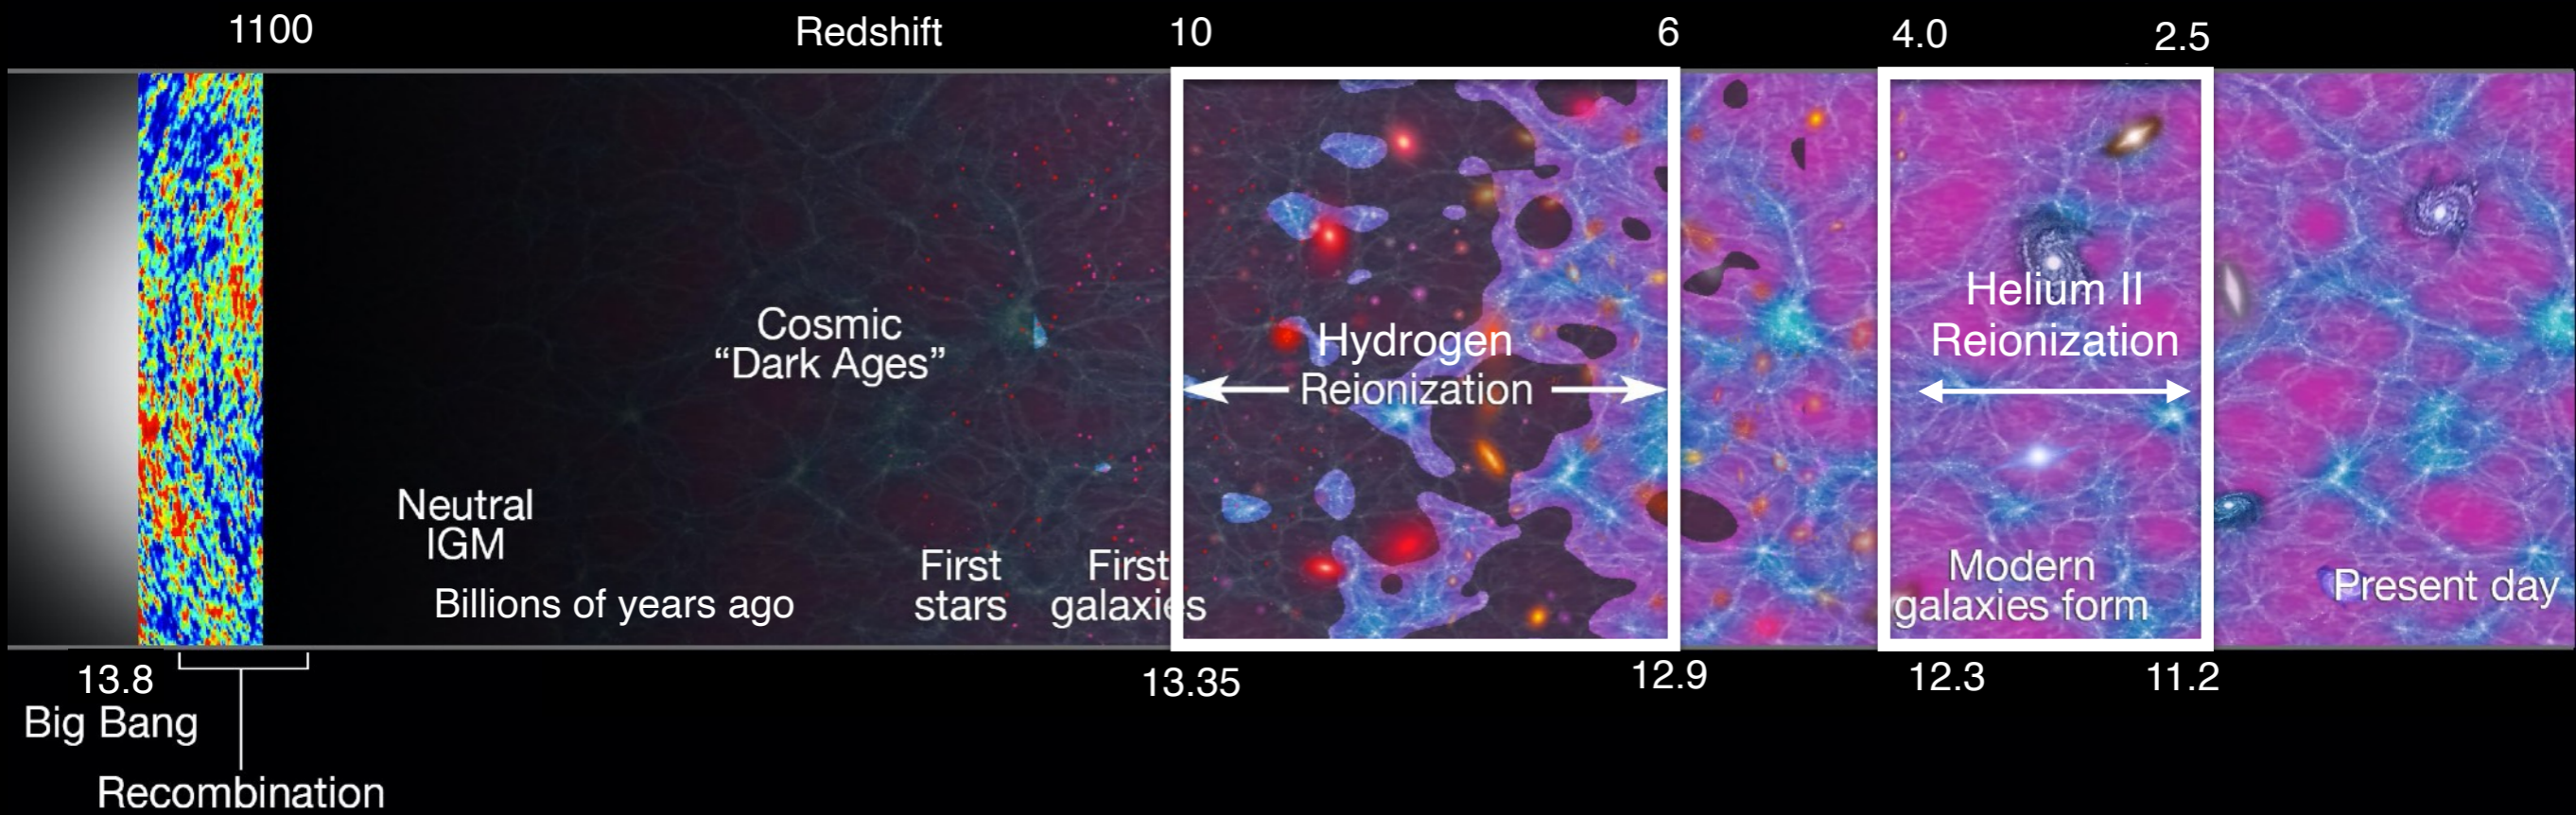

BH-BH merger density within design advanced LIGO sensitivity ($z < 2$) for models M10.B (old $Z(z)$) and M60.B (new $Z(z)$). Top panel shows distribution of individual BH masses, while bottom panel shows total BH-BH system mass.

Evolution of the mass-metallicity relation using [Zahid et al](#) (as in Madau & Fragos) and [Ma et al. 2015](#) (based on simulations). The attached plot (for 3 stellar masses, $\log M_*=7,9,11$) shows that the major difference is in the zero-point rather than in the redshift evolution — except perhaps at $\log M_*=11$.

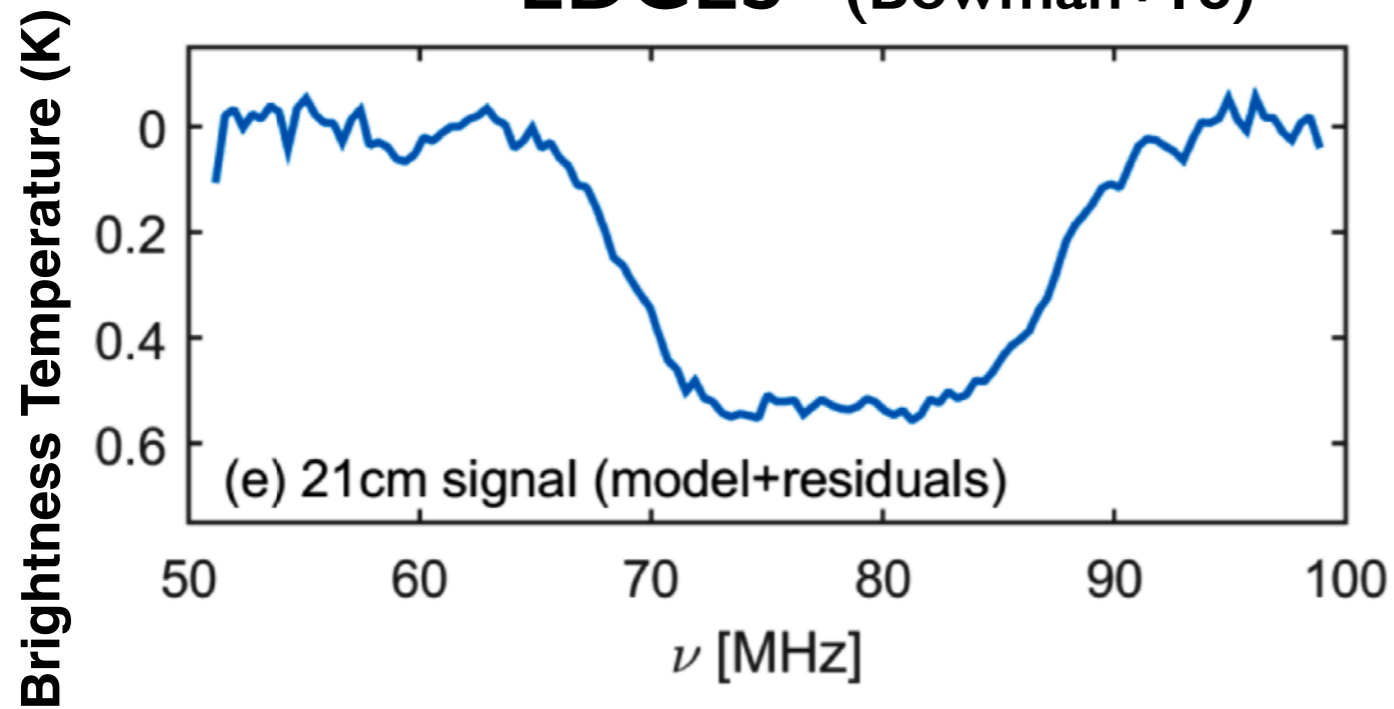

A BRIEF HISTORY OF REIONIZATION

WHEN DOES REIONIZATION START?

EDGES (Bowman+18)

$$T_{21} \propto x_{\text{HI}} \left(1 - \frac{T_{\text{CMB}}}{T_S} \right)$$

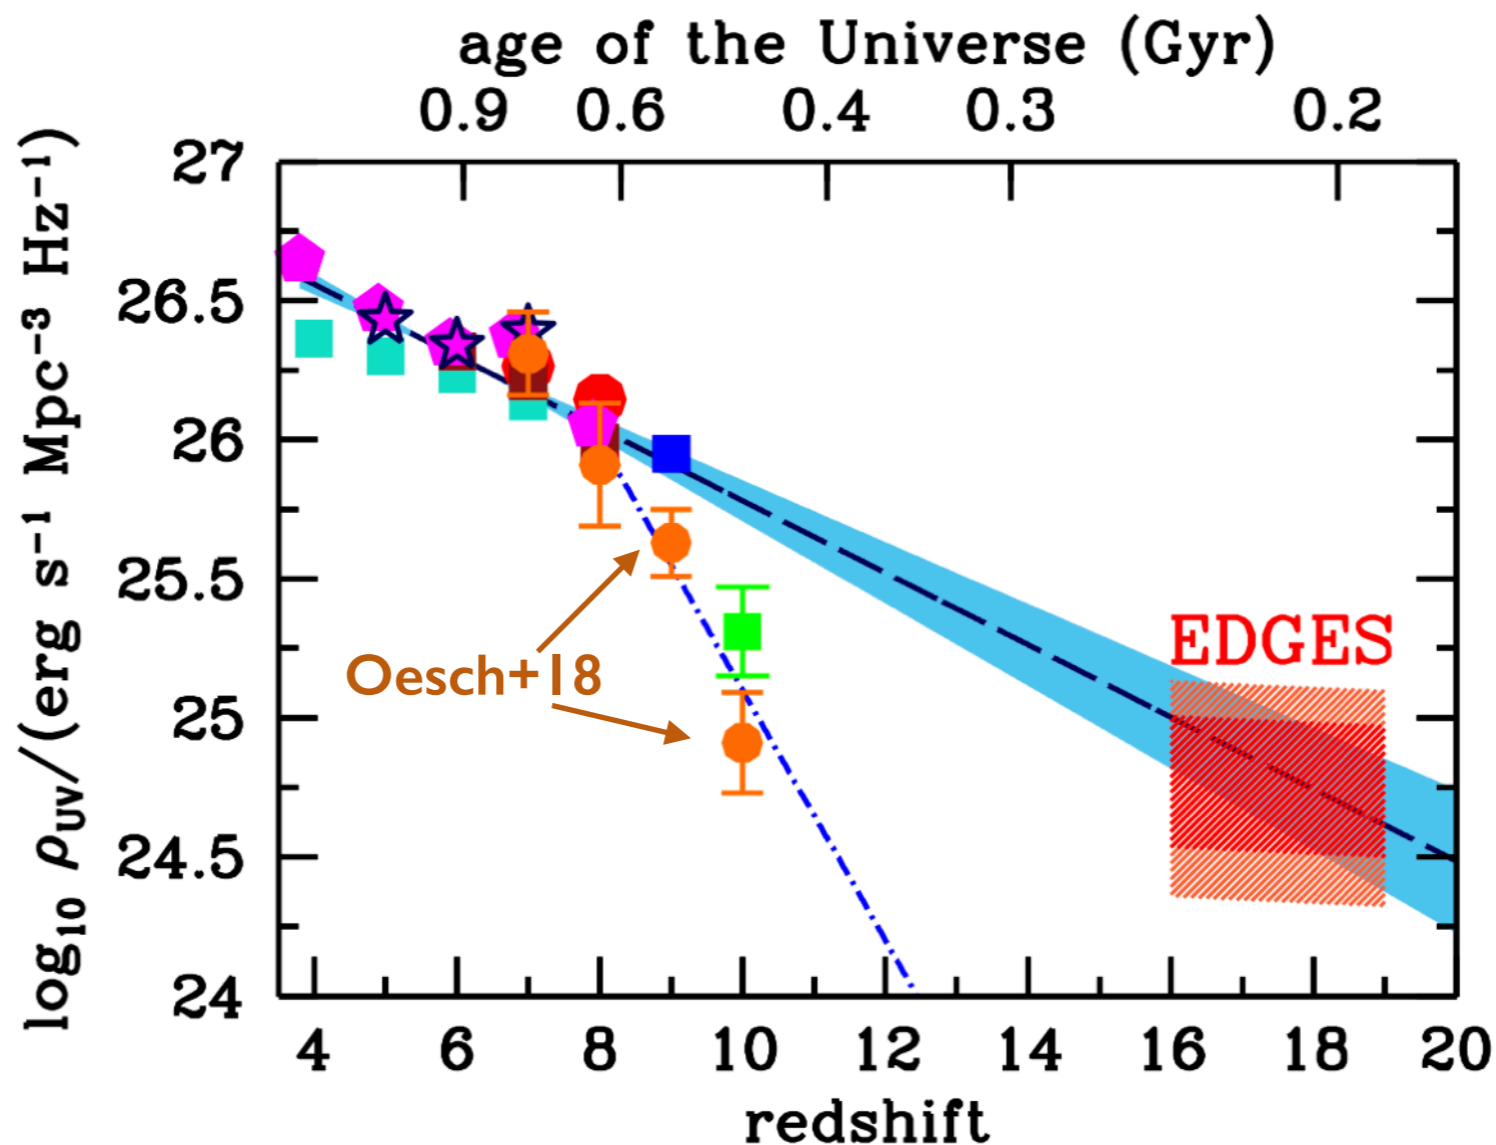

(assumes no excess radio background!)

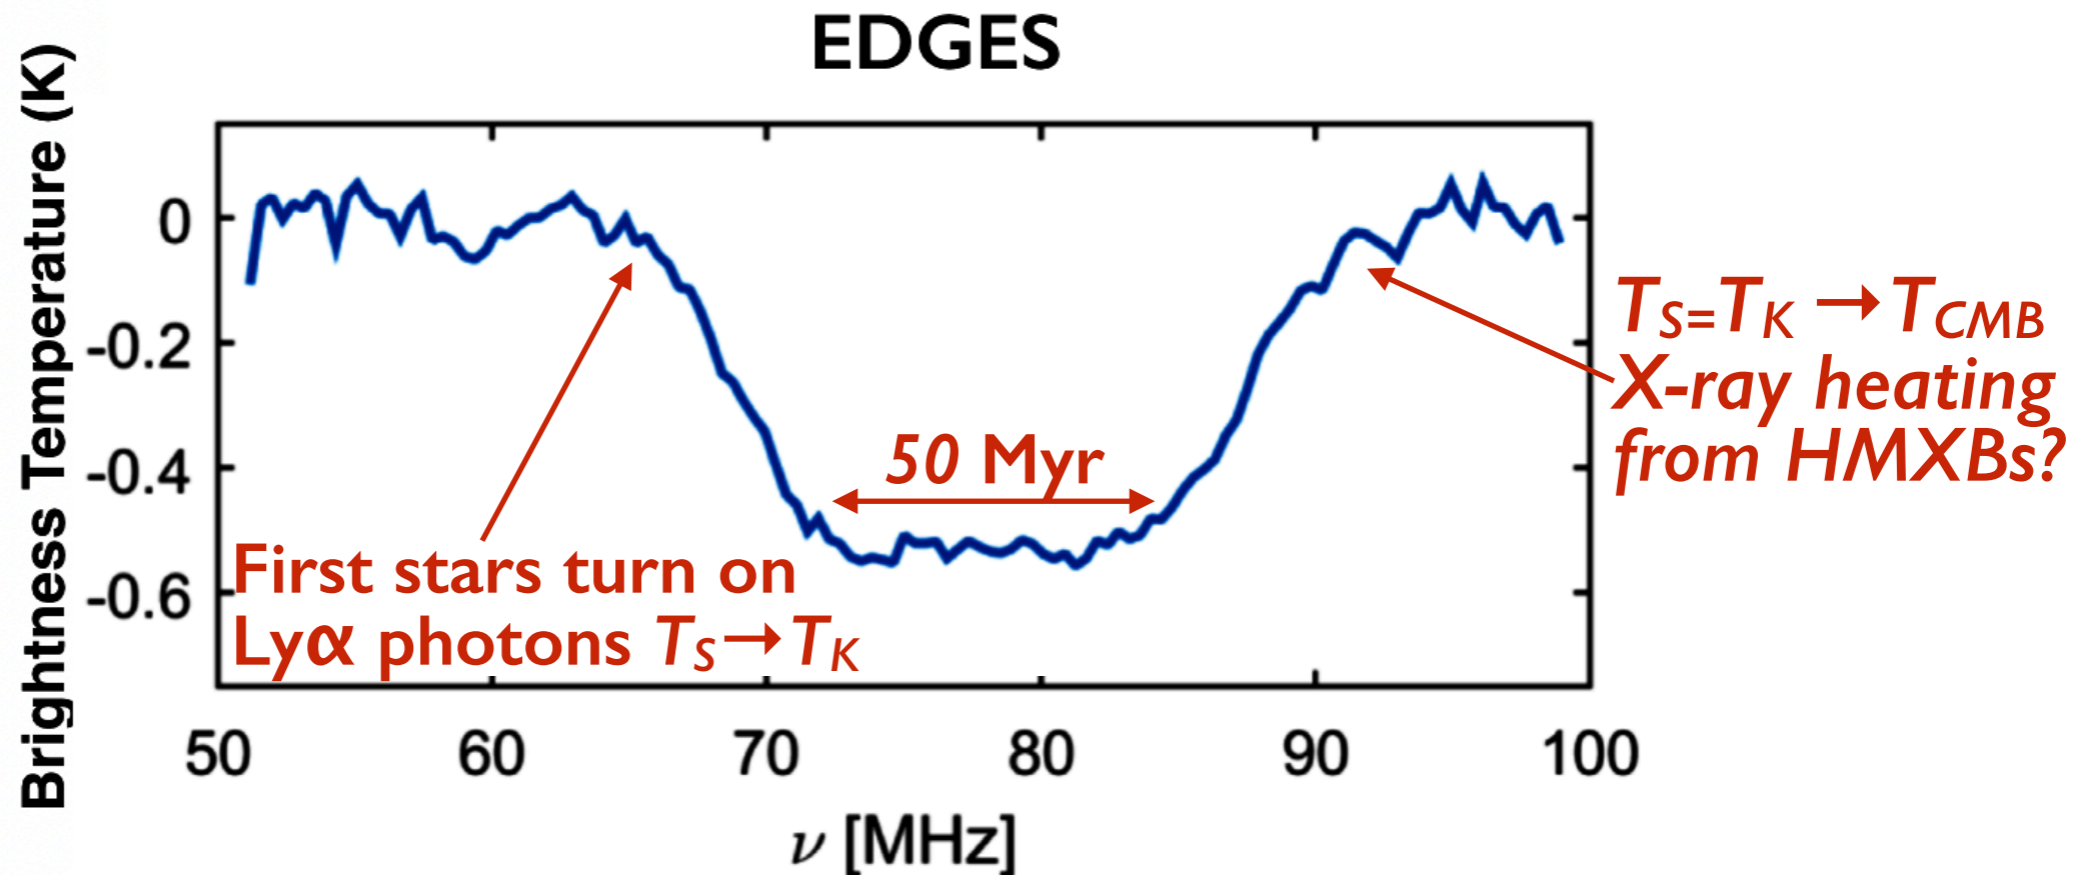

FIRST, METAL-POOR STELLAR SYSTEMS?

A 21-cm signal at $z \sim 18$ is consistent with an extrapolation of the declining galaxy UV luminosity density measured at $4 < z < 9$ by deep HST observations. *A substantially enhanced SFR density or new exotic sources of UV photons are not required by the EDGES detection.*

☛ galaxy light builds up at a steady rate over the first Gyr of cosmic history?

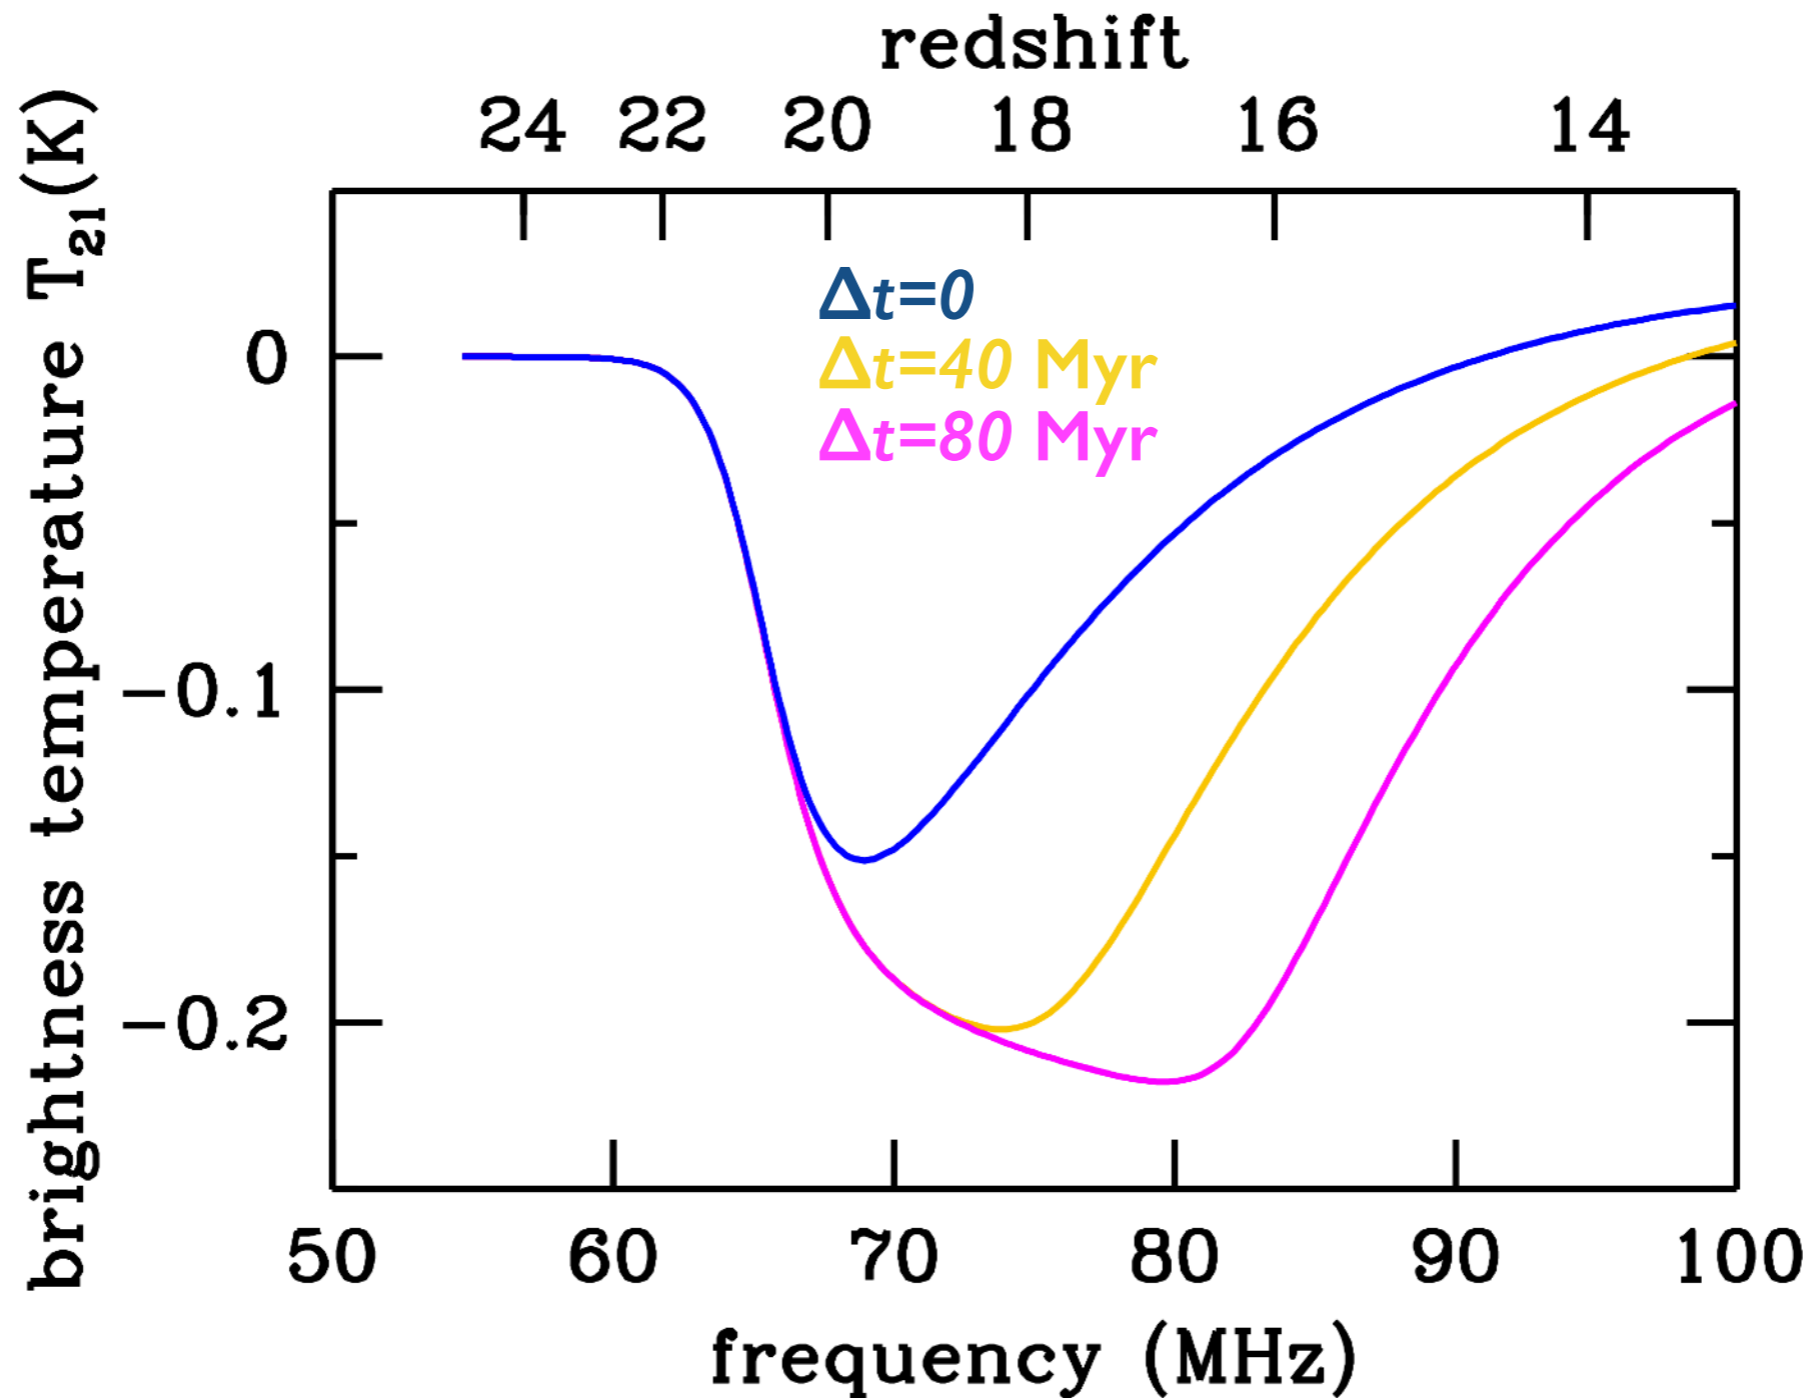

X-RAYS AT COSMIC DAWN?

Δt = preferred formation timescale of HMXBs after SF episode.

M33 (Garofali+2018, HST+Chandra): $\Delta t \sim 40$ Myr (delayed onset associated with NS+Be stars).
